ABSTRACT

This thesis investigates the possibility of employing computer spreadsheets as a sophisticated tool to resolve resource allocation dilemmas through simulation techniques. *Microsoft's Excel 4.0* is used to analyzed three separate and unique resource allocation problems. First, an inventory distribution system involving different distribution points to illustrate the magnification of uncertainty as the distribution system is lengthened. Second, queuing utilization problem faced by an emergency room of a hospital. The third scenario looks at the uncertainty in financial budgeting situation as reflected in the Navy's CHAMPUS budget. A spreadsheet macro using simulation techniques is created for each scenario to illustrate that computer spreadsheets are fully capable of analyzing resource allocation enigmas through simulation methodology.

I. INTRODUCTION

Within the Department of Defense and business world, one facet of a manager's success is his/her skill at formulating an appropriate balance among the scarce resources at his/her disposal. Sagacious allocation of limited resources are paramount to the success of a manager. Multiple methods exist and are at the disposal of a manager for guiding him/her to the most feasible solution. One of the instruments available to the manager for resolving a resource allocation dilemma is simulation. Simulation is a methodo'ogy that handles uncertainty and presents the manager with the best possible solution among several feasible alternatives. The most simplistic simulation model involves elementary mathematical equations and events that can be formulated and solved by hand. However, most applications of simulation in a real world setting are too complex for hand calculations and thus require the implementation of digital computers with simulation specific software. The simulation method that is appropriate for each predicament is a function of the complexity of the problem and the time constraints faced by the decision maker. Hand simulation is time consuming and often impossible to solve. Simulation specific packages employing a digital computer will solve a majority of problems. Unfortunately, simulation oriented software is not as widely applied as it can be due its prohibitive cost or technical skill needed to develop a simulation program.

A. PURPOSE

The purpose of this thesis is to confront resource allocation through simulation methodology by using a conglomeration of simplistic and complex methods. Digital computer spreadsheets, which are available to virtually every manager, can be applied to perform simulation. A link between computer spreadsheets and simulation will allow a

broader application of simulation methodology by managers. This thesis will focus on the methods for applying computer spreadsheet simulation for solving relatively complex resource allocation predicaments. This study is structured to answer one primary question: How applicable are off-the-shelf digital computer spreadsheets for resolving resource allocation problems employing simulation methodology?

B. SCOPE

The focus of the study will be limited to discrete vice continuous simulation techniques. The distinction between discrete and continuous systems is required because of the entirely separate discipline existing concerning the study of continuous systems. Models of continuous systems are an industrial process integrated over a period of time resulting in the mathematical formulas containing differential equations. Discrete systems involve product industries that can be quantified into discrete events thus requiring simplistic mathematical equations. Problems requiring the application of differential equations should be solved with simulation specific software. Thus, the analysis will be conducted using the digital computer spreadsheet software *Microsoft Excel 4.0 for Windows*. Excel 4.0 is currently the most powerful off-the-shelf spreadsheet software available and is compatible with other available spreadsheet software

C. OVERVIEW

In order to comprehend the simulation method, simulation philosophy will be introduced in Chapter II. The chapter will also describe how simulation can be used as a resource allocation tool. Chapter III introduces terms, builds upon the simulation philosophy, and develops the methodology required for construction of simulation models. Throughout the chapter, simulation methodology as it pertains to computer spreadsheets will be discussed in order to develop guidelines for building models. Chapters IV, V, and

VI will illustrate the previous chapter's guidelines for computer spreadsheets. Three different scenarios will be modeled and analyzed using simulation. Chapter VII presents the conclusions of the research.

II. SIMULATION AS A RESOURCE ALLOCATION DECISION TOOL

Simulation methodology is one of several tools available to the manager for providing feasible solutions to the enigma of allocating scarce resources. Before discussing the many benefits of analyzing resource allocation problems through simulation techniques, one must first become familiar with the alternative methods that are available and practiced by managers. When presented with a predicament concerning the apportionment of assets, how does a manager arrive at a decision?

A. TOOLS FOR RESOURCE ALLOCATION

A significant number of the decisions made by managers when facing almost any issue are founded upon his/her previous experience or intuition. A manager's experience accumulates throughout his/her career and can originate from many sources. The acumen of professional consultants, professional literature, and successes or failures both he/she and his/her competitors have encounter in the past are just a few of the sources of experience. Decisions arrived at by intuition are more difficult to rationalize. However, a decision based on a "gut feel" has been encountered by almost everyone. Recurrently, a manager encounters a decision that he/she has no experience to reflect upon for a solution. What methods are available to a manger if he/she has no previous experience or no desire to commit resources solely upon intuition?

One method a manager has at his/her disposal if he/she does not have any experience to reflect upon is to create a knowledge base for his/her decision. Knowledge is developed by performing experiments on the actual system that he/she lacks knowledge and observing the responsive behavior. The system that is modeled can be any set of interdependent elements that function within an organization to meet specific goals, i.e.,

allocation of resources. Experiments consist of proposing and applying changes to variables, policies, or scenarios that effect the system. The resultant consequences and behavior of the system manipulation are analyzed and further changes are considered and acted upon. Through these iterations of experiments, experience is developed and a final decision or policy is settled upon.

This method, often called "trial and error," has its drawbacks. Trial and error on the actual system can be expensive, time consuming, and even detrimental. Thus, one can rarely perform experiments in the business world. Even if the opportunity exists, if the system does not yet exist, experimentation is not a feasible alternative. A manager must apply other methods to develop experience.

Analytical techniques are another method for decision analysis and involve the application of mathematical equations that have been derived by management scientists. The system in question is studied and a mathematical model is constructed that represents the interactions of the system and environment. The relevant equations are solved using simultaneous equations and calculus techniques resulting in an optimal solution. An optimal solution is the best solution among several feasible solutions. The manager can then institute his/her decision or policy. However, a few caveats must be considered when a manager chooses the analytical approach. First, the system may be amenable to a mathematical model but deriving the solution may be beyond the capabilities of the manager or his/her staff. Second, as a model more closely simulates reality, i.e., becomes increasingly more complex and mathematical techniques becomes incapable of fully describing the system. Thus, another tool is required to resolve these dilemmas.

B. SIMULATION FOR RESOURCE ALLOCATION

To solve analytical enigmas, the next alternative available to managers is the world of simulation. Simulation methodology is the development of a mathematical model or a

series of models that describes the behavior of a system over time. Thus, simulation is heavily dependent upon analytical techniques and offers a method of solving analytical problems that are beyond the manager's capabilities. Many other benefits exist with simulation, but simulation is not an end in itself. It is a vehicle from which data for further analysis is collected and conclusion drawn. It does not replace the experience and intuition of the manager but instead it is an augmentation to the information available to a manager.

The two preeminent advantages of simulation in comparison to previously discussed methods are imitation of reality and reduced expense. Imitation of reality is a key concept and an advantage of simulation because it allows a manager to observe the behavior of a system as he/she induces change without agitating the real system. Thus, the difficulties encountered with actual experimentation are mitigated. The manager can now observe behavior of a simulated system and will be able to determine the system's sensitivity to changes in key variables, locate critical factors or problem areas, and evaluate the effectiveness of his/her decisions. Thus, a manager can derive effective solution before the actual implementation of an unproved policy or action. Also, during a simulation exercise, he/she can control many features of a system that he/she would not usually control in a real world setting. A manager can develop experience by relating known manipulation to known results.

Concerning expense, simulation offers several economical benefits. By use of digital computer simulation methods, a manager can evaluate alternative ways of meeting objective in a fraction of the time that would normally be required for the long term effects of a proposed decision to occur in time. Time is money and simulation methods allow the manager to be in control of time. He/she can compress time so as not to wait for the passage of time to produce results. Second, manipulation does not occur with an actual

system in which costly mistakes and pitfalls could occur. He/she can gain experience at the expense of a simulation model vice the organization's capital. Furthermore, if the system is in the design stage and does not yet exist, simulation allows for cost benefit analysis of hypothetical situations. The manger can derive an economical design founded upon simulated results. Construction of a system need not be based upon an intuitive guess or a faulty experience. Also, simulation produces data inexpensively which can be used for further analysis.

Therefore, simulation is a viable and essential tool for approaching all but the most simplistic of resource allocation problems. Simulation methodology provides the manager with the best of all feasible alternatives without committing an organization's capital. Additional consideration must be given to the low cost associated with simulation. The next section discusses how a manager applies simulation as a tool.

C. SIMULATION THROUGH COMPUTERS

Assuming the manger understands the benefits of simulation methodology, how does he/she most effectively implement simulation techniques? Simulation can range from very simplistic methods involving the development of a solution by hand to the most complex that require the application of digital computers and simulation specific languages, i.e., GPSS and SIMSCRIPT to name a couple. Unfortunately, for a majority of managers, the hand technique becomes either too complex and time consuming or the computer oriented method is too expensive and beyond the manager's skills. Thus, he/she must consult a simulation programming expert to solve his/her problems, if one is available. Another approach would be the marriage of simple and complex techniques through the application of off-the-shelf computer spreadsheets to solve all but the most difficult simulation quandaries.

Digital computer spreadsheets were first introduced with the development of Visicalc by Dan Bricklen and Bob Franston in 1979 [Ref. 1]. Visicalc did little more than replace pencil and paper calculations with a computer. However, during the past decade, computer oriented spreadsheets have grown exponentially in functionality and computing power. Through spreadsheets, a manager has the ability to produce powerful simulation models. All the manager needs is knowledge of simple spreadsheet procedures and an understanding of basic principles of simulation methodology. Currently, the most popular off-the-shelf spreadsheet software is Lotus 1-2-3, followed by Excel. Each provides limited simulation ability by employing "what if" analysis. Thus, simple simulation is available to anyone who owns a microcomputer and a spreadsheet package.

However, "what if" analysis is limited to a few variables and does not address time or probabilistic issues that are essential criteria for simulation methods. These limitations can be resolved through the purchase of inexpensive simulation "add-in" programs such as Simulated Solution, @RISK, or Crystal Ball, or by spreadsheet programming through "macro" commands. Add-in programs are not widely available to most managers, but the basic spreadsheet program is available to virtually all managers. Accordingly, Chapter III will explore the applicability and development of computer spreadsheets for solving moderately complex simulation problems using simulation methodology and spreadsheet macros. In addition, guidelines for the development of computer spreadsheet simulation models will be identified for application to other resource allocation problems.

III. SIMULATION METHODOLOGY

This chapter outlines the methodology entailed when developing and applying simulation models and digital computer spreadsheets to resolve resource allocation predicaments. The chapter will begin by summarizing relevant simulation oriented terminology followed by a discussion of an effective strategy for a manager who embarks upon the creation of a simulation model. When appropriate, concepts, suggestions, and command specific to *Excel 4.0* (adaptable to other off-the-shelf spreadsheets) will be provided to assist a manager on his/her macro programming endeavors.

A. TERMINOLOGY

The following terms are employed throughout the course of this study and will be defined here so as to avoid any confusion in terminology.

- 1. System: The system is any set of interdependent elements that function within an organization to meet specific goals. A system may have subsystems.
- 2. Model: The model is an imitation of a system using formulas, logic statements, etc., that when conglomerated represent how the system physically interacts within reality.
- 3. Discrete: A discrete system has events that occur during a specific point in time. Time is considered as a distinct unit vice continuous with events flowing from one to the next.
- 4. Stochastic: A stochastic system entails estimates on the part of the decision maker of events or variables that are random or probabilistic in nature.
- 5. Deterministic: When variables are assigned a single-valued estimate vice a stochastic estimate, they are considered deterministic.

- 6. Exogenous Variable: Exogenous variables are entered into a model and are not altered in value during the simulation exercise. An exogenous variable is also referred to as an *environmental variable*.
- 7. Endogenous Variable: Endogenous variables that are dependent upon the interactions within the simulation model. Their values are derived by the model during the simulation and are often referred to as state variables.
- 8. *Policy Variable:* Policy variables are variables that obtain their value as a direct result of the decision makers' intervention.
- 9. Flow Chart: A flow chart is a graphical representation using boxes and arrows to represent events within a system as events progress through time.

 Interactions between variables, environment, etc., are captured within a flow chart.
- 10. Feedback: Feedback is the transferring of output back to the input so that policy variables can be altered in an attempt to obtain a desired output.
- 11. Routine: A collection of computer commands that perform a function or functions.

B. SIMULATION STRATEGY

Simulation philosophy is a methodology of approaching management allocation predicaments. Unfortunately, there is no specific procedure that a manager can apply due to simulation models being unique in application and must be designed anew with each new kind of problem. However, there are commonalties between problems and models that facilitate a strategy when a manager confronts the task of simulation. Thus, during the construction of an effective simulation model, the person who develops the model will proceed through a logical progression of steps. Some steps will be easier than others and consume less time while others are more difficult and time consuming. However, all are necessary as each step depends upon the preceding one. The remainder of the chapter will lay out the steps required for an effective strategy when addressing all but the most complex simulation scenarios.

1. Define the Problem

Essential to the success of a simulation model is the definition of the problem that the manager wishes to simulate. He/she must pose the question: "What is my objective for the model?". The objectives must be clearly stated so that the manager or programmer can assess the purpose of the model with its resultant desired output. Initially, the definition may be broad, such as a plan to minimize cost with the system. As the model progresses through the following steps, the objectives will become more narrowly defined as different aspects and objectives are realized. However, with a defined objective, a programmer can proceed to the next step of charting the interactions within the system.

2. System Flow Charts

Capturing the essence of a system that is required to properly develop a simulation model is best done through flow charts. Before describing flow charting techniques, one must first understand basic system relationships. Figure 3.1 illustrates the

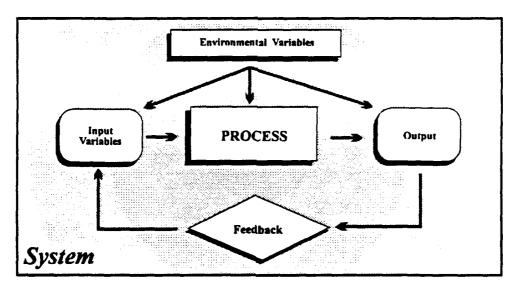

Figure 3.1: System Interactions

interactions that exist within a system. Key to the success of the simulation model is the proper identification of interactions shown in Figure 3.1. The *environment* is beyond the control of the decision maker but it interacts with all facets of the system and must be understood. The decision maker controls the *inputs*, monitors *feedback*, and makes decisions through policy variables. The *process* is the heart of the simulation model where most of the functional interrelationships are understood and then programmed. With a stated objective and a basic understanding of the system in terms similar to Figure 3.1, a basic flow chart can be constructed. [Ref. 2:pp. 2-4]

The first flow chart will capture the essence and general interactions that are involved in the system. It should be a relatively simple chart as it will become the foundation from which all other interactions and flow charts are constructed. The first flow chart will be the backbone of the simulation model and it is upon this that a master control routine is created. Subroutines branch out from the master routine to perform more specialized tasks or functions. This logic of breaking the system into one master routine and several subroutines is ideal for "debugging" a model. The technique of routines and subroutines is discussed later.

When developing flow charts, a manager should only consider key variables and interactions. Once a working model is created, more complexity and realism can be added as needed. The greater the number of endogenous, stochastic, and policy variables included in a model, the more complex the model becomes. This results in an increase in the time required to develop and run a simulation model. However, with an increase in complexity the model becomes more accurate. The more accurately that the model represents reality, the more accurate the results and the closer the simulation will be to meeting the objectives. This trade-off between time and accuracy is partially determined by the objectives and partially from the experience of the programmer. With the flow

charts drawn and thoroughly understood, the programmer continues to the next step of simulation strategy.

3. Mathematical Modeling

Mathematical modeling often coincides with the creation of flow charts. This occurs because mathematical models involve functional relationships where exogenous variables (inputs) are transformed into values for endogenous variables (outputs). Also, the functional relationships will be an integral part of the boxes within flow charts. Mathematical modeling is also the point in the simulation process where the discipline of spreadsheet modeling becomes a consideration. A programmer must be continuously thinking about how he/she is going to program the spreadsheet to recreate the mathematical and functional relationships.

During the mathematical modeling phase, a number of sources are referred to for equations and relationships. Several equations will be used that have been created by management scientists for analyzing a problem using analytical techniques. This is the case for the inventory distribution and queuing models discussed in the next two chapters. Other sources will be from the discipline from which the model is formulated such as general accounting relationships. Other functional relationships are developed by understanding the relationships inherent within the flow charts created for the system. The purpose of mathematical and functional relationship modeling is to describe the system as carefully as possible. Each equation or relationship describes a relationship between two or more factors of interest in the system. When consolidated, they represent the flow charts and eventually the complete system.

Critical to the mathematical modeling phase are the assumptions that are built into the simulation model. What is considered to be generally understood and in what situation will the simulation model be exercised? A caveat must be considered at this

point in the discussion. Anyone who deals with simulation must understand that the model is only as genuine as the input and the assumptions inherent to the input. A poor assumption will invalidate the model no matter how well the model is constructed. As the saying goes, "Garbage in gives garbage out!" Therefore, the importance of this step in model development cannot be over emphasized.

Another consideration that must be understood during simulation construction is the unexpected. A model should take into account every conceivable value of the system being considered. For simplistic models, it is easier to prevent values or place limits within the model. For example, if the stock level in an inventory system achieves a certain level, the simulation should perform a function or end simulation. The reasoning behind this logic is the difficulties a programmer will encounter if a condition is forgotten and is encountered during the simulation. Numerous hours of debugging can result from an unaccounted value or a condition that results in misleading and invalid output.

4. Creating a Spreadsheet Simulation Macro

This step is the point of divergence from a typical approach to simulation methodology. Instead of applying a spreadsheet to solve a simulation oriented problem, the traditional approach is for a manager to choose hand simulation or simulation specific computer languages to solve his/her resource allocation dilemma. If the problem under consideration is a continuous situation vice discrete, simulation specific languages are the optimal choice. However, the focus of this thesis is on moderately complex, discrete scenarios that lend themselves to spreadsheet simulation. The remainder of this chapter will be oriented towards the application of a spreadsheet for resolving of resource allocation problems. In particular, techniques developed during this study will be presented to the reader to augment his/her spreadsheet simulation endeavors.

However, before launching into the programming phase, the programmer must become intimately familiar with the capabilities of the spreadsheet he/she intends to employ. Spreadsheet; are not designed to be used for simulation tasks but are fully capable to do so through macro programming. However, one must be creative in programming the spreadsheet to perform simulation. The more that a programmer understands the capabilities of his/her spreadsheet, the easier the task will be.

After constructing flow charts and mathematical relationships, the next task, often the most time consuming, is the creation of the simulation macro(s) and worksheet within a spreadsheet program such as Excel 4.0. Careful preparation and forethought will save the programmer several hours of debugging during the creation of the program. However, debugging will be required no matter how efficient the programmer is. The following paragraphs are techniques that will help the manager solve resource allocation problems using Excel or other off-the-shelf digital computer spreadsheets.

a. Subroutines

To facilitate debugging, ease of understanding, and use of flow charts, a "master" macro should be created. The master macro will control the entire simulation process through a network of supportive subroutines. The master routine should be constructed upon the basic or central flow chart. It should control time and its respective iterations along with output and input of variables. The subroutines should be developed to perform specific or several functions of the flow charts or separate blocks within flow charts. The concept of "block-building" through subroutines facilitates debugging by limiting the areas where a programmer must look for difficulties.

A subroutine does not have to be part of the same macro. It can be its own separate macro that is initiated by the master or other subroutine macros. Separate macros become a necessity with complex scenarios that require many lines of

programming code. Otherwise, the program becomes too large, difficult to debug, and some functions of *Excel* become limited or lost. Also, *Excel's* group editing abilities allows the editing of several macros simultaneously, thus saving time.

b. Variables

Several techniques exist for assigning values to variables. For exogenous variables that are deterministic and not changed for different scenarios, the best command to use is SET.VALUE(reference, values). For variables that need to be updated during simulation and recorded in a separate location on the spreadsheet, the best command to use is FORMULA(formula_text, reference). Exogenous and deterministic values that are changed by the user for different scenarios or assumptions are entered through a function referred to as DIALOG.BOX(dialog_ref). This command presents the simulation user with an interaction box similar to Illustration 3.1. Dialog boxes can be used for a number of other functions such as prompting the user for input needed for policy variables.

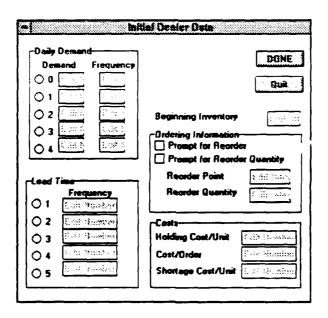

Illustration 3.1: Sample DIALOG BOX

Another function of *Excel* that is used for variable manipulation is the IF(logical_test, value_if_true, value_if_false) command. Using this command, variables (i.e., cell reference to itself) can cumulate data when a condition is either true or false as shown in Illustration 3.2. IF(..) is also used for stochastic events and Monte Carlo

	A	В	С
	name	command	comments
333	Total Type 1	=IF(Patient Type=1,Total Type 1+1,Total Type 1)	Tally Patients
334	Total Type 2	=IF(Patient Type=2,Total Type 2+1,Total Type 2)	
335	Total_Type_3	=IF(Patient_Type=3,Total_Type_3+1,Total_Type_3)	

Illustration 3.2: Data Culmination

techniques. By using multiple IF(..)s, a stochastic variable that has been converted to a cumulative relative frequency is coupled with a RAND() function to generate a random number less that one. The MAX(number1, number2,..) function then determines the value. This process is depicted in Illustration 3.3.

c. Naming Variables and Locations

A powerful capability of spreadsheets is the ability to name cells or blocks of cells. Thus, a cell that is being used as a variable can be assigned a name.

Naming should be used as much as possible to permit the programmer, debugger, and user to better understand the program. Instead of trying to determine which cell a formula is referenced to, a name is utilized. DEMAND and Demand_Table are examples of using names as shown in Illustration 3.3.

d. Recording Data

Computer simulation involves the passage of simulated time in a compressed format. The gathering of output statistics during simulation requires an ability to record data either in computer memory or on the spreadsheet for further analysis. This can be done through a couple of methods. The first is to collect data using IF(..), MAX(..), etc., functions as shown in Illustration 3.3. The disadvantage of this method is that the data for each particular iteration is lost. However, it is ideal for simplistic Monte Carlo methods or for the summation of information.

The second method is to record the information in a spreadsheet matrix format. Unlike simulation languages that support three-dimensional storage of information in computer memory, a spreadsheet requires the recording of information after each iteration onto the spreadsheet. This is the major difficulty that was encountered when applying spreadsheets for simulation problems. It was not impossible but requires some creative programming to resolve some of the perplexities encountered.

When using a matrix format to store data, one needs to have the ability to reference a location on the spreadsheet. The OFFSET(reference, rows, cols, height, width) command was used extensively for this function. For the reference, the corner cell of the matrix was assigned a name for easy reference. Therefore, a two dimensional matrix was accessible on the worksheet for data storage and manipulation.

e. Manipulation of Time

The method by which time is controlled within the macro that controls the spreadsheet simulation determines the foundation upon which all macros are constructed. The idea is to move the model through time to see the dynamic behavior of the system. The simulation begins at time zero where all parameters have their initial values as provided by the user. As time progresses during simulation, various events occur causing changes within the model. Thus, time is central to the simulation. Two methods of time management were used in the examples in the following chapters.

The first method is to allot time into fixed units. Time is then iterated using the FOR(counter_text, start_num, end_num, step_num) function with its corresponding NEXT() until the user inputted time limit is reached. This was used for the simulation of inventory distribution and financial management problems.

The second method is a "next event" technique [Ref. 3]. Time is not iterated in fixed units but instead is iterated by the time required until the occurrence of the next event. Next event methods require more creativity in program design so that each event can be traced with its respective information. The method employed in the queuing examples was a two-dimensional pointer-matrix methodology. Each event was assigned a time and a pointer that maintained the location of relevant data.

f. Logic Statements

For situations that require a separate set of actions based upon different conditions, Excel offers several logic functions. For example IF(logical_test),

ELSE.IF(logical_test), and ELSE() allows the program to execute separate functions due to three separate conditions. The function WHILE(logical_test) with its corresponding NEXT() permit localized iteration routines if required. Each of these functions lends themselves to conditional requirements within flow charts.

These above techniques are the major methods that were developed during the creation of the models contained in the next three chapters. Other techniques can be discovered in the program listing contained in Appendices A, B, and C.

5. Validation of the Model

Once a working spreadsheet model is created, the most difficult task for the programmer is validation and debugging of the model. Essentially, given inputs with corresponding known correct outputs (this can come from an organization's past data or hand calculations) are entered into the model and the model's output is scrutinized. Other methods of debugging also can be employed. Excel has a built-in add-in function for debugging. This add-in permits the insertion of breaks within the macro or check points where values of critical variables can be called up and their validity determined. Another function that was found to be invaluable was the macro utility bar. Contained on this utility bar is a function that allows an individual to "step" through each individual line of the macro. Thus, a programmer can validate that every line of programming in the macro is performing what it was designed to do. The utility bar also allows the pausing of a macro. This facilitates repositioning of the computer display of the macro or worksheet to check on other sections of the spreadsheet during simulation execution.

One who begins programming will learn that the validation phase is the most difficult and rewarding. As he/she progresses through every conceivable scenario and situation, a simulation model will be created. Often, at this point, further complexity is added to the working model to enhance the accuracy of the model until the final simulation model is created.

6. Model Implementation

Once a model is created and validated, the model should be put to use and the benefits of the simulation realized. Often the model is further modified to add more

realism or to meet new objectives. One will find that the first model is the most difficult. Fortunately, as time progresses and experience is gained, the process becomes much easier.

The next three chapters present the application of simulation and computer spreadsheets for analyzing resource allocation problems. Techniques discussed in these chapters are used to create spreadsheet simulation models for three unique allocation scenarios frequently confronted by managers. Each will demonstrate how "what if" analysis through spreadsheet simulation can provide economical guidance to managers when making crucial policy decisions. Spreadsheet simulation provides management with the capability to analyze how a decision effects a dynamic system without the expense of trial and error.

The simulation systems chosen for illustration and discussion are inventory distribution management, queuing environment utilization, and a financial budgeting scenario. Before discussing each simulation model, an introduction is provided outlining the dilemmas faced by managers and the apropos solutions provided by management science theory concerning the aforementioned illustrations. With an understanding of the traditional solution to each resource allocation problem, the alternative approach of simulation will be introduced to illustrate how simulation can augment management science theory. The logic behind each spreadsheet simulation model will be discussed followed by scenarios demonstrating the power of each model. Each scenario's result will be analyzed to conclude each section.

IV. INVENTORY DISTRIBUTION MANAGEMENT

This chapter is the first of three chapters that present applications of simulation and computer spreadsheets for analyzing resource allocation problems. The first resource allocation to be discussed is a dilemma that often confronts managers. How to effectively develop a set of rules and policies for managing inventory? Inventory can be best summarized as the items that are maintained in storage to meet the immediate and future demands within the organization or by customers. Almost all institutions possess some form of inventory. Inventory can become extremely large and consume a majority of the capital assets available to the manager. Therefore, the expertise of maintaining inventory capital at a minimum while simultaneously ensuring that the demands of the organization and its customers are satisfied is a crucial facet of a successful manager.

A. THEORY

Inventory management is an aspect of management science that has been analyzed and documented in literature for decades. Management scientists have developed several analytical models to assist a manager in achieving a balanced and economical inventory management system. The central thrust of these models is to apply analytical techniques to achieve a theoretical balance between desirably low inventory levels with that of sufficient stock to meet customer requirements. Ideally, the analytical results will allow a sagacious manager to achieve positive customer relations and the lowest possible commitment of assets. This requires few or no backorders with low inventory levels. Unfortunately, analytical methods are formulated under the presumption of ideal conditions such as predictable demand and lead time. With the introduction of reality, the manager must augment an ideal solution with experience or other methods to obtain an

efficient inventory system. It will be shown that spreadsheet simulation can be a valuable tool in enhancing a manager's experience.

Before introducing inventory simulation, a manager must understand inventory management theory. The overall objective of the analytical method is to achieve the lowest commitment of assets. The commitments of capital in the form of costs are as follows:

- 1. Holding or carrying costs that are essentially the expenses of physically having an inventory within the organization. Examples of these costs are floor space, insurance, and obsolescence. Holding costs do not include the actual value of the inventory. [Ref. 2:p. 56]
- 2. Ordering (or setup in a production environment) costs that are incurred with each decision to order (or produce) more inventory. Examples of these costs are clerical costs associated with processing an order, shipping cost, and material handing costs once the order is received, or the costs of restarting the production line after a temporary shut-down. [Ref. 2:p. 57]
- 3. Stockout cost that consists of forgone profit, lost sales, or the cost of an emergency order associated with the inability to meet customer demand when an item is not available. This cost is the most difficult to estimate and often is the most expensive. [Ref. 2:p. 57]

Once a manager has assessed the costs involved in maintaining an inventory, an understanding of how the costs interact is required to illustrate the purpose of analytical techniques. The first interaction is that holding and order costs move in opposite directions. Assuming ordering costs are greater than holding costs, a manager who makes large orders will decrease the total cost of ordering. However, large orders result in higher inventory level, thus increasing holding costs to the point that will eventually

exceed the benefit of reduced ordering costs. The second interaction is that stockout costs will decrease as order size increases but are more a function of the reorder point vice quantity. If a manager maintains his/her inventory levels low to reduce holding costs, the potential exists to order too late, resulting in items being out of stock with a corresponding exponential increase in stockout costs. These conflicting interactions lead the mangers to ask themselves two questions: How much should I order? and When should I order?

The traditional method in management science for resolving the manager's questions is to apply analytical techniques referred to as the Economic Order Quantity (EOQ) model. This model, with algebra and differential calculus, will identify the most economical balance between order quantity and reorder point. However, as previously discussed, adding more realism and complexity to a scenario will result in the traditional analytical methods of analysis becoming prohibitively difficult to apply, even for professional mathematicians and statisticians. Thus, to cope with reality, managers rely upon experience to determine a sufficient safety or buffer stock. However, a buffer stock result in a higher reorder point and excess inventory. Determining the level of safety is not an easy task because the best set of rules often cannot be established in advance. The rules for determining an appropriate safety stock must often be arrived at through the process of trial and error. However, by applying simulation and spreadsheet analysis, a significant reduction in the costly methods of guess work and trial and error can be achieved by the manager.

B. INVENTORY DISTRIBUTION SIMULATION

The inventory distribution system model that was developed using Excel 4.0 is designed to simulate a typical factory to dealer distribution system with multiple levels of warehouses. A discussion of the logic behind the model is included in this section. A full

listing of the model's macros and comments are provided in Appendix A. The model is designed for analysis of multiple scenarios. A relatively simplistic model consisting of one dealer with non-probabilistic lead and demand times demonstrating EOQ theory can be analyzed. Additionally, the model is capable of allowing the user to analyze extremely complex scenarios with up to three warehouses, probabilistic demand and lead times, and continuous involvement by the user. Complex scenarios illustrate the difficulty of applying EOQ techniques for achieving optimal solutions. Many different aspects were considered and included within the spreadsheet model. Furti modifications to the macros can be performed to include any degree of realism within the simulation. However, the extent of modifications to the model for further capturing the richness of a real-world situation should not be so complex that the user cannot understand or appreciate the spreadsheet simulation model for analyzing a managerial problem.

Before constructing the inventory distribution simulation, one must first determine the objectives of the model. What do we wish to examine? The following model was designed to analyze inventory level, backorder and cost behavior that are the critical aspects of inventory management system. A model that demonstrates these behaviors will augment a manager's policy concerning when and how much to order under different scenarios.

With the model's objectives in mind, a number of flow charts were created to build and chart the sequence of events that were required to properly understand an inventory distribution system. The first flow chart developed gives a broad summary of how orders generated by the customer are received by the dealer and then progress down through the distribution system to the factory. The result is merchandise being provided to the customer. This progression of orders from the customer to the factory is illustrated in Figure 4.1. The flow of events is different if less than three warehouses are included in the

simulation. Instead of the orders and inventory flowing between warehouse #3 and the factory, this event may occur between warehouse #1, #2 or more, depending upon the number of warehouses simulated.

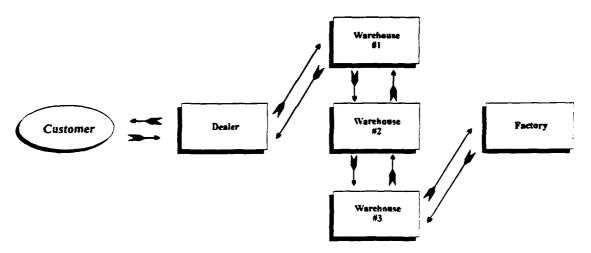

Figure 4.1: Inventory Flowchart

The flow of events is a generic representation of inventory distribution systems which can be found in the private sector or military logistic supply systems. For example, the supply department on a ship performs the same function as a dealer in the private sector. The shipboard supply department receives customer demand from the onboard customers it was designed to serve, such as O-level maintenance facilities.

Key to the flow of events is the treatment of "time" within the model. For an inventory system, time is a fixed unit. Thus, each iteration through Figure 4.1 is the passage of one time unit and all other elements are treated as variables. On the other hand, a queuing model, which follows this chapter, treats time as a variable with other elements being fixed. Thus, time becomes the critical element in the development simulation model and will lead to vast differences between models.

To simulate an inventory distribution system with time as a fixed unit, one worksheet and six macros were created within Excel 4.0. The worksheet is a place holder

for the data and graphs created by the individual macros. The worksheet accesses the macro by two macro command buttons. One button begins the simulation routine, while the second transfers the data to the graphs for analysis. The six macros perform the actual computational work of the simulation. Five of these six macros are for each of the inventory management centers depicted in Figure 4.1 except that the customer is included within the dealer macro. The sixth macro is the master macro that controls the process of interactions among the five individual inventory management macros and is the first macro to be executed when the user begins the simulation from the worksheet

As shown in Figure 4.2, the first action by the master macro is to display an initial input dialog box requesting information on inventory status and policies such as reorder

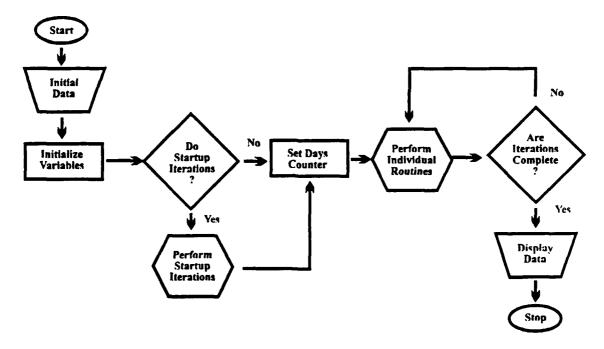

Figure 4.2: Master Macro Flow Chart

point, order quanity, holding costs, etc. This is the information required for performing a simulation. Additionally, the number of warehouses desired and how much user involvement is needed during the simulation is requested by the input dialog box. Options

of involvement range from none, with the exception of initial data, to complete control requiring every decision to be made by the user during the simulation. Once the master macro has the information required to perform the simulation, it begins an iterative process of progressing through each macro as shown in Figure 4.2.

If startup iterations are desired, the master macro will iterate without any user involvement thus producing random inventory and backorder levels. This option is useful for the full involvement scenario as it adds another level of complexity to the problem. Once the initial data and startup segments are performed, the macro begins an iterative process for the number of days requested by the user. The master macro's first step in the iteration is to call upon the dealer macro that initiates the inventory distribution process. When the dealer macro returns control to the master macro, an iteration is complete and time is incremented by one unit. The process then repeats and continues until the number of iteration days is complete. The last function of the master macro is the transferring of data back to the worksheet.

The dealer macro initiates the inventory distribution system. It, along with each of the warehouses, has virtually the same flow chart of events occurring as illustrated in Figure 4.3. The first calculation that is performed by the dealer but not the warehouse macros is to calculate customer demand that is either probabilistic or deterministic. With demand known, the macro will then fill any backorders if inventory is present. What is left of current inventory is applied to the customer's order and if insufficient, a backorder log is developed. With the remaining inventory, the macro makes the determination if inventory is below the reorder point. If this is the case, an order is placed at the warehouse. The order will be received by the first warehouse depending upon the lead time that is probabilistic or deterministic. Even if there is no order placed, the dealer macro calls upon the warehouse macro at this point to permit updates of the warehouse

and factory inventory levels. The last function of the macro is to determine if a previous order has arrived. If so, it is the added to the inventory.

The warehouse macro differs from the dealer macro in that it does not calculate customer demand but instead receives its orders from the dealer. Furthermore, each warehouse will call upon the next warehouse in the distribution chain or the factory, depending upon the number of warehouses in the simulation.

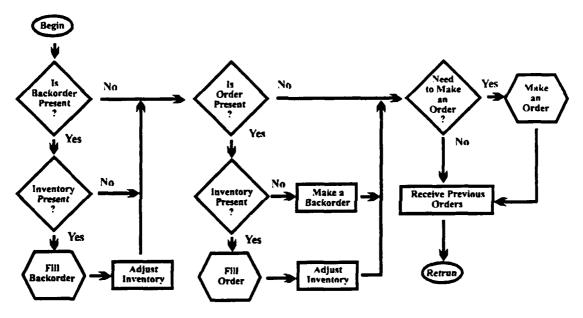

Figure 4.3: Dealer and Warehouse Macro Flow Chart

The flow of events for the factory macro is illustrated in Figure 4.4 and is slightly different in design and concept than the dealer and warehouse macros. Instead of making the decision to place an order, the factory macro makes the decision to either startup or shutdown production. The same logic as reorder point is applied. Production will begin when inventory level depletes below a certain level and production stops when inventory exceeds a certain level.

Common to the entire macro chain is the concept of macro nesting. This means that customer's order precedes through the inventory management system in a linked like

manner. The order starts at the dealer on Day 1 and continues through the warehouses reaching the factory at an unpredictable date. This time-delay effect on each inventory management point amplifies the uncertainty in customer dem. I and illustrates the need to use simulation models to examine the effect of different inventory policies at different management points. Once at the factory, the order reverses direction back to the dealer as illustrated in Figure 4.1. Another element of the system is that each successive iteration within the model is the passage of one time unit that equates to a single day. However, the user can assume any length of period as long as input data regarding demand rates, lead time, cost parameters, and so forth are appropriately scaled. The output will then reflect the time unit chosen by the user.

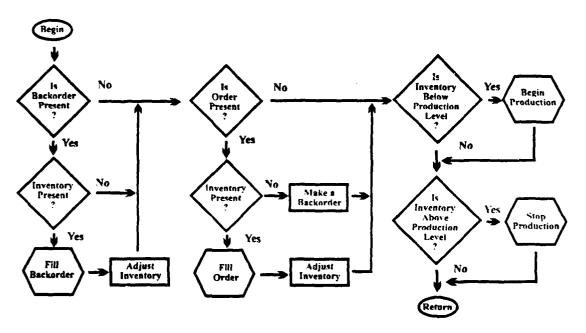

Figure 4.4: Factory Macro Flow Chart

C. SCENARIOS

With an understanding of the logical progression of events and how functions of each macro, four different scenarios will be analyzed to demonstrate how the simulation

spreadsheet model can be used to augment the manager's expertise concerning inventory management. Each scenario could be solved using analytical and hand simulation techniques. However, as the level of complexity increases, it becomes apparent how a computer spreadsheet facilitates multiple "what if" analysis in a fraction of the time required to obtain one analytical answer. Each simulation will be a dynamic system showing the interactions and oscillatory behavior typical of a dealer to factory inventory distribution system over a sixty day period. Sixty days with initially low levels of inventory are chosen to force an oscillatory behavior to occur early within the simulation. The purpose of each scenario is to demonstrate how the spreadsheet simulation technique can be applied to illustrate oscillatory behavior and derive possible optimal solutions vice gathering reams of data.

The oscillatory behavior may be transparent to a manager involved with only one aspect of the distribution system. He/she may not appreciate how small changes in retail demand often create large swings in factory production and warehouse inventory that far exceeds the fluctuation of retail demand. These fluctuations can be quite costly due to employment instability, over capacity, and high inventory levels. Through simulation, a manager can manipulate variables without experimenting on the actual inventory levels. He/she will see how simple changes in variables and policies can have dramatic effects upon the system as a whole. The three scenarios chosen manipulate variables only slightly, yet each has its corresponding oscillation.

The first three scenarios will begin with the same initial data but will have varying levels of complexity. The first two will involve no user involvement with the exception of entering initial data. The first scenario will have only one warehouse between the dealer and the factory while the second will have three warehouses. The third scenario will also have three warehouses but will demonstrate the maximum complexity capable of the

simulation model. There will be ten startup iterations to allow for random levels of inventory and backorders. Additionally, all orders and factory production decisions will be decided upon by the user during each iteration. The fourth scenario will be similar to the second but instead lead times will be significantly reduced. This reduction in lead times will demonstrate a Just-In-Time (JIT) inventory distribution system. The results of each simulation scenario are discussed in each section and complete output graphs are provided in Appendix A.

1. One Warehouse, No User Involvement

For each of the four scenarios, the same initial input data was used as shown in Table 4.1. The initial reorder points and quantities are chosen to be large and late so that an initial oscillatory behavior is demonstrated early within the model. Furthermore, the factory's inventory level is twice that of the others to absorb the initial surge in demand. The factory's production rate is sufficient to exceed demand, therefore providing an illustration of startup and shutdown events at the factory.

TABLE 4.1: INITIAL INPUT DATA

	Dealer	Warehouses	Factory
Beginning Inventory	50	50	100
Reorder Level	25	25	•
Begin Production Level	*	•	35
Stop Production Level	*		100
Amount of Order	25	25	25
Rate of Production	•	*	30
Holding Cost	\$.10	\$.10	\$.10
Order Cost	\$20	\$20	•
Setup Cost	•	•	\$100
Shortage Cost	\$50	\$50	\$50

Having only one warehouse between the dealer and the factory is the simplest of the four scenarios, thus one would expect very little oscillations. This would be the

case if demand and lead time were not probabilistic. A simple EOQ calculation would allow the dealer and the managers of the warehouse to determine economic order point and level resulting in relatively stable inventory patterns. However, all four scenarios have both demand and lead time being probabilistic as provided in Table 4.2. The latter column of relative frequency lead times was used in the final scenario to represent a JIT environment.

Having probabilistic demand and lead times without user input results in multiple orders being placed before receiving any shipments from previous orders. This is the primary reason that large oscillations in inventory levels occur as illustrated in Figure 4.5.

TABLE 4.2: DEMAND AND LEAD TIME FREQUENCY

Demand	Relative Frequency	Lead Time	Relative Frequency
4	20	1	20/90
5	29	2	20/10
6	20	3	20/0
7	20	4	20/0
8	20	5	20/0

Additionally, even after achieving large inventories by day twenty, strong demand with corresponding late ordering again results in a depletion of the dealer and warehouse inventory by day thirty. Consequently, the dealer and especially the warehouse develops significant and expensive backorders. By altering the reorder point and levels, an optimal solution can be obtained. However, by adding levels of warehouses to the scenario, the difficulty in predicting demand and oscillatory behavior make obtaining a solution even more illusive.

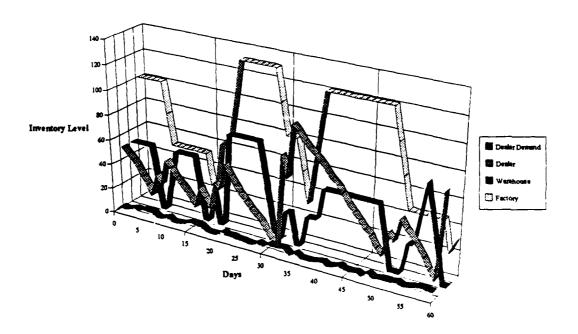

Figure 4.5: Scenario 1—Inventory Level with Probabilistic Demand and Lead Time

2. Three Warehouses, No User Involvement

By adding more warehouses to the scenario, the oscillations in inventory levels permeate throughout the inventory management system and are significantly more pronounced as illustrated in Figure 4.6. The fluctuations are similar to a one warehouse scenario. However, with three warehouses, the increased interdependence compounded with probabilistic lead time result in inventory level rapidly depleting to zero. These low inventory levels cause several backorders and a corresponding increase in overall cost for this inventory distribution scenario. So, how should the managers reduce costs?

The complexity of Figure 4.6 fully demonstrates the difficulty of applying traditional analytical techniques to derive an economical solution. By understanding the behavior of the system through simulation with graphical outputs, the manager can develop and test policies in an attempt to reduce cost. The display of inventory levels in Figure 4.6 reveals some inventory patterns. First, all three warehouses rapidly deplete

inventory to zero as the dealer and warehouses quickly order to increase inventory. A policy to resolve this dilemma would be for each warehouse to have a higher reorder point. Another apparent pattern is that the factory's inventory is decimated as all three warehouse order simultaneously. Additionally, the factory rapidly cycles through the phases of production. Solutions to these difficulties range from producing larger quantities with corresponding long shutdown periods or by decreasing production rate.

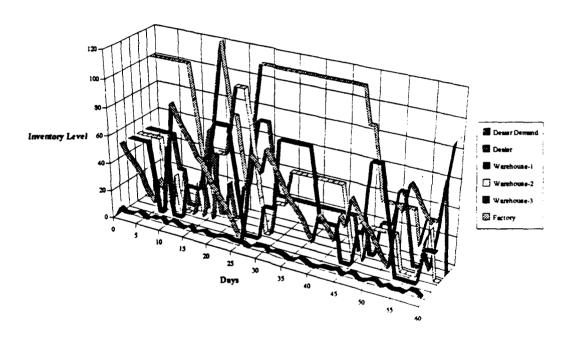

Figure 4.6: Scenario 2—Inventory Levels with Probabilistic Demand and Lead Time

To test these possible remedies, many "what if" analysis can be performed to find the most economical policy for each warehouse, the dealer, and the factory. These particular scenarios assume that order and order points were set and did not change during the simulation. The next scenario will demonstrate the increased complexity involved when each manager attempts to maintain an inventory at a level that mitigates backorders when faced with random demand.

3. Three Warehouses, Full User Involvement

With the exception of ten startup iterations, this scenario differs from the previous scenarios in that the program does not automatically reorder for the dealer or warehouses nor does it automatically start or stop production at the factory. As the simulation iterates through each successive day, the user must make the decision to order or alter factory production based upon inventory level and demand. The dealer and warehouse managers will try to keep their inventories at a sufficient level considering average demand. If inventory levels begin to fall below a desired level the manager will order extra units above his/her sales rate to rebuild the inventory. Conversely, he/she will reduce his/her order rate if inventory level becomes too high. Accurate prediction is limited due to probabilistic demand and lead time. The dealer can estimate demand to stay within a certain range. However, the warehouse managers will find it difficult to predict how much the previous person up the chain will order and when. Additionally, whenever an order is placed it can arrive up to five days later thus giving the potential of zero inventories with corresponding backorders.

The resultant inventory behavior of the three warehouse scenario with user involvement is illustrated in Figure 4.7. Oscillatory behavior is still present but the initial fluctuations are due to the beginning inventories being artificially low for the corresponding demand. Furthermore, the ten startup iterations developed random inventory levels and backorder and do not allow user intervention. The first twenty days demonstrate low to zero inventory levels as the dealer and the warehouses build inventory to approximately one hundred units. Furthermore, inventories do not increase until factory production is sufficient and inventory arrives according to probabilistic lead times.

Once inventory levels are stable, the demand upon the warehouses diminishes.

The managers then begin reducing inventory to a more optimum level of approximately

eighty. However, warehouse #2 and #3 waited too long and allowed inventory to depleted to zero and incurred momentary backorders. The practice of reducing inventory levels to reduce holding cost without continuous orders leads to the oscillatory behavior. Running this simulation for a greater period would allow each manager to determine an appropriate reorder point and quantity at the least cost.

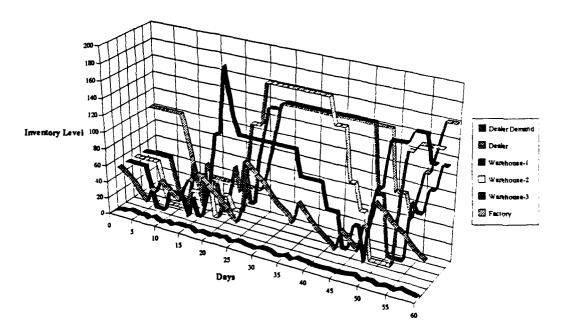

Figure 4.7: Scenario 3—Inventory Levels with Probabilistic Demand and Lead Time

In this scenario, it is cheaper to have an abundant inventory to minimize cost. However, scenarios with increased holding costs will make it more difficult to predict which policies will give the optimal solution. Additionally, a Π T model will illustrate that reduced inventory are more economical. The benefit of the simulation model is to demonstrate the difficulties involved with maintaining an inventory distribution system but allows the managers to experiment with different decision options and evaluate the potential consequences. The three-dimensional graphs illustrate the oscillatory behavior of

a distribution system and give the manager an appreciation of the dynamics and interactions involved between each of the individual units.

4. Three Warehouse, JIT Environment

When a JIT environment is simulated, the difficulty in predicting lead time by the manager is mitigated, allowing for more stable inventory levels. An examination of Figure 4.8 reveals that inventory levels remain relatively constant. The occasional jump shown by

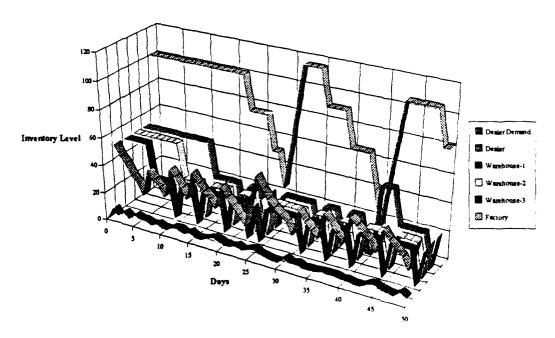

Figure 4.8: Scenario 4: Inventory Level Under JIT

the dealer and warehouse #3 are a result of lead time being two days vice one. Therefore, inventory level is below the reorder point two days in a row and subsequently two orders are made. The resultant double order by the dealer causes warehouse #1 to face a backorder with its high penalty cost.

A drawback of the depicted JIT scenario is that the multiple orders cause the overall cost of the system to gradually rise. This could be solved by varying order points

and levels to achieve a more economical solution. However, the point of this scenario is to have the same initial data as the other scenarios for comparison. Furthermore, the predictable behavior of Figure 4.8 is the crucial aspect of JIT that should be understood by a manager. The predictability allows a inventory distribution manager to derive a superior inventory policy. This is one of the reasons that many organizations, including Navy Depots, are converting to a JIT inventory distribution system. This is especially the case if holding costs far exceed ordering costs.

Each of the above scenarios illustrate the benefits a manager can derive from spreadsheet simulation modeling of an inventory distribution system. The next chapter will demonstrate how spreadsheet simulation can augment a manger's ability to analyze resource allocation within a queuing environment.

V. QUEUING ENVIRONMENT UTILIZATION

As with inventory management, effective allocation of resources within a queuing environment is another challenge often faced by managers. A queue, or waiting line, is the accumulation of customers, products, etc., at a holding station that are awaiting service or processing within a system. Any institution that provides services or engages in manufacturing and faces the possibility of an item waiting in line deals with some form of queuing utilization. Inventory, for example, is provided to the customer by a server. If a sufficient number of attendants are not available to the customer for delivery of merchandise, excessive queues develop and the customer will seek service elsewhere. The manager may have determined the optimum stock levels required to prevent stockout but his/her analysis would be incomplete if the queue consists of people. If the queue is too long, customers waiting in line would become dissatisfied with the system. The result is lost sales that are the equivalent of stockout costs in an inventory environment. Thus, another facet of a successful manager is the ability to make crucial decisions in the realm of queuing theory.

A. THEORY

Queuing discipline can be approached in many ways with as many corresponding solutions as demonstrated in the previous chapter on inventory management theory. The most rudimentary approach for determining the number of servers or processing stations required for the expected demand is to use trial and error methods. By changing a few parameters and observing the results, a manager can determine the most economical balance between desired service capability and customer waiting time. As the system increases in complexity, it often becomes impossible to achieve an optimal solution through

trial and error techniques. Furthermore, if one is designing a new system, such as the number of registers to install in a grocery store, it is not economical to render a guess as to an optimal solution. Therefore, other methods are required such as analytical and simulation techniques for solving more complex scenarios. However, one first must understand some basic aspects of queuing theory as developed by management scientists.

In discussing queues, several common terms are used. A *queue* is that part of the system where units are waiting service. The *server* is the person or device that performs a service to the units waiting in the queue. The *system* itself consists of all queues and servers. *Channels* are the lines within a system that can be simple in nature with a single line or more complex with multiple channels. The number of servers contained within a channel are referred to as *phases*. As with channels, a simple system will have a single phase while more complex systems contain layers of servers or multiple phases. Another term common to queuing systems is *balking*. Balking occurs when queues become too long and the customer chooses not to wait in line. He/she either seeks service elsewhere or comes back at another time. To determine when balking occurs is often difficult to estimate but critical to the design of a queuing system. [Ref. 2:pp. 172-174]

With a knowledge of queuing phraseology, one must also understand queuing discipline. What is the sequence of events within a queue and how are these events distributed with respect to time? Common to most queues is the design of the system that provides service to the first item within the queue or sometimes defined as "first come, first served." Other service philosophies can be used in the design of a system such as assigning categories to items in the queue and serving some categories above others regardless of when they entered the queue. Given a service philosophy, one can assign the proper distribution of events in relation to time. The best approach is to observe the actual system in operation over the period of time that analysis is desired and simulate arrivals to fit the

observed pattern. If this option is not available or it is a new system, other models are used within queuing simulations. For arrival rates, a Poisson distribution with its corresponding negative exponential probability of arrival has been found to fit a majority of arrival patterns. If a Poisson arrival distribution is not appropriate, another approach is to model arrivals through a normal or uniform distribution. For service times, observation is the best choice. However, a normal distribution is often used if an observation is unavailable. If a more appropriate distribution function exists, it can be used to model service time.

In choosing the number of servers in a model, one must be careful not to allow arrival rate to approach service rate. As arrival rate nears service rate, an exponential relationship occurs resulting in chaos and the queuing system collapsing upon itself. This potential exponential growth in the queue often does not occur in the real world due to the onset of balking significantly before model failure.

Once the parameters are chosen and the system is properly modeled, the approach offered by management scientists for developing an optimal solution is the application of analytical techniques. As with inventory management, analytical techniques consist of several formulas that provide an understanding of the behavior of the queuing system. Through the behavior of a system, the cost involved in providing the services can be minimized. The costs that must be considered are:

- Service costs. These are the expenses a manager must consider in providing the desired service. These costs include the cost of the material required for providing the service as well as the salary of the employee.
- Waiting costs. These expenses are faced by the manager when units are forced
 to queue as they await service. These costs include opportunity costs as well as
 balking costs.

Service costs are often easy to calculate but waiting costs can be much more illusive. Furthermore, waiting costs can sometimes be inappropriate such as with a hospital environment. Instead of placing a value on human life that would occur with balking and possible death, a minimum service level is determined and used to obtain an optimal solution. However, even with a thorough understanding of the queuing formulas, many queuing systems are too complex to be solved using traditional analytical techniques.

Thus, one must pursue simulation methods to derive an optimal solution.

B. QUEUING SYSTEM SIMULATION

The queuing system that was simulated using Excel 4.0 is a highly complex analysis of a hospital emergency room. The hospital emergency room that was modeled includes multiple phases and multiple channels. The complexity is further compounded by using a modified "first in, first serviced" philosophy by accounting for patients who need immediate care. The arrival rate of patients employes a Poisson distribution that varies over time. The number of nurses and doctors in the emergency room for treating patients varies during time to deal with changing levels of staff workload during a day. Additionally, five different patient types are considered to model varying levels of treatment and service rates by the nurses and doctors.

To solve this queuing problem and multiple "what if" scenarios, one could use analytical techniques. However, deriving an analytical solution would consume vast amounts of time. An analysis of a one week scenario using the model developed took approximately thirty minutes on a high speed personal computer. Performing several "what if" scenarios consumed several hours and illustrates the benefit of computer simulation. Furthermore, as with the inventory model, several parameters can be manipulated within the model to simulate different scenarios. A full listing of the program with comments is provided in Appendix B.

The primary challenge in the design of a spreadsheet queuing model is how to account for the sequence of events in relation to time. Unlike the inventory model, time is not a fixed event to which all other events are linked. With a queuing system, time is a variable that is controlled by all other events and is governed by a "next event" discipline. For each iteration, the model does not increment time to determine what happened during the fixed time unit but instead asks the question, "What happens next?". To use the technique of "next event" timing, the model iterates time backward instead of forward. Each event is assigned a completion time that is incremented to zero by another event's completion. The event whose time is closest to zero is the next event to which action occurs and triggers all other events.

To catalog events and their times of action, events are classified as either primary or secondary. A primary event causes action to occur in the model such as arrival of a unit or the completion of service. Secondary events, such as entering or leaving a queue, are a direct result of primary events. Additionally, the occurrences of primary and secondary events result in the scheduling of other primary and secondary events in a chain-like manner. To fully understand this concept requires the use of a flow chart that depicts the passage of a patient through the emergency room as illustrated in Figure 5.1. Flow charts

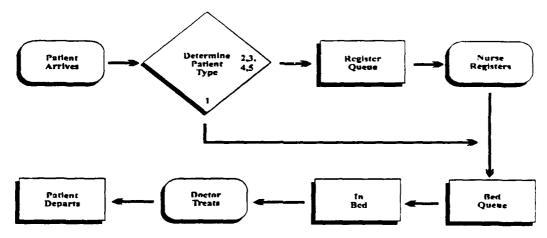

Figure 5.1: Chain of Events for a Patient

are also provided for each primary event with its corresponding chain of secondary events. Rounded rectangles within Figure 5.1 contain the three primary events that occurr within the the hospital emergency room. The three primary events that can occur with each patient are the arrival to the emergency room, the completion of registration by a nurse and the completion of treatment by a doctor. Several secondary events occur as a result of these primary events but first a discussion of Figure 5.1.

Figure 5.1 shows the chain of events that occur for each individual patient within the hospital emergency room. The first primary event to occur is his/her arrival. The chain of events for the primary event of a patient arrival is illustrated in Figure 5.2. A Poisson arrival distribution was used to simulate arrival rate. Other arrival distributions could be modeled through the altering of a few programming lines in the spreadsheet macro. For

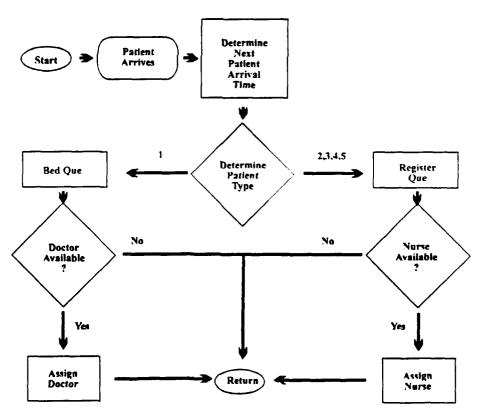

Figure 5.2: Primary Event—Patient Arrival

"next event" time philosophy, a secondary event is to calculate the arrival of the next patient. Each arrival to the emergency room was calculated using a negative exponential distribution. The parameters for the calculation are time of day and mean arrival rate. This calculated arrival time is used as a count down time for the next patient's arrival. Another secondary event is the determination of the patient medical classification or type. This value determines if the patient goes straight to the bed queue (open wounds, i.e., type 1) or to the registration queue (less sever cases, i.e., types 2 - 5). Within each respective queue, a determination is made as to whether a nurse or doctor is available respectfully. If either is available, the patient is removed from the queue and is assigned to a server. The nurse or doctor is then assigned a normal distribution treatment time based upon patient type.

The next primary event to occur is that of a nurse completing registration of a patient with its corresponding secondary events as illustrated in Figure 5.3. The first secondary

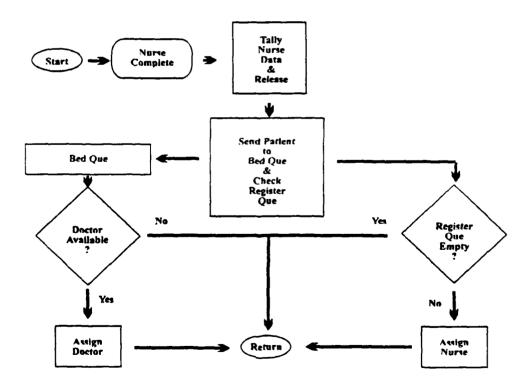

Figure 5.3: Primary Event—Nurse Completion

event is to collect data on the nurse's service (i.e., time spent with patient, etc.) followed by a freeing of the nurse for further patients. The registered patient is sent to the bed queue and is assigned a doctor if one is available. The free nurse is assigned to another patient if one exists in the registration queue. If assigned, a service time is determined as previously discussed. The service time is used for the next event analysis.

The final primary event within the model is the completion of service to the patient by the doctor. The secondary events are shown in Figure 5.4 with the first event being the

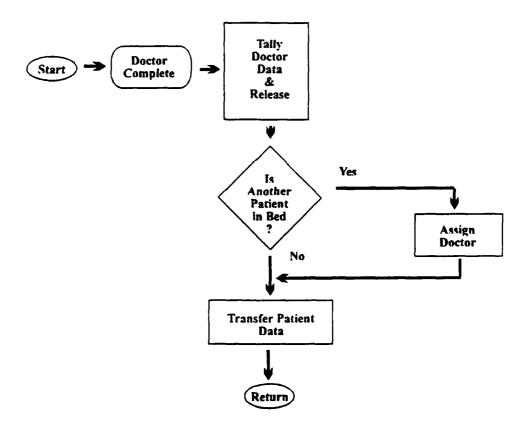

Figure 5.4: Primary Event—Doctor Completion

tallying of doctor statistics. The doctor is then freed for treating further patients. The information on the treated patient is transferred to a location of the spreadsheet for later analysis. The final event is to check if another patient is in bed who needs treatment. If so,

the doctor is assigned a completion time as previously discussed with the time being used for next event analysis.

By understanding the primary and secondary events within the hospital emergency room, a spreadsheet simulation model can be developed. Similar to the inventory model, one must first establish the objectives of the simulation. The primary objective of the model is to collect a number of statistics that can be analyzed by the user to determine the behavior of the system and facilitate human resource (i.e., doctors and nurses) allocated and assignment decission. Another objective is to provide a number of options to the user to accommodate "what if" analysis. The spreadsheet model that was developed allows a number of different choices for optimization of hospital queuing problems. Choices vary from the number of nurses and doctors available (up to four each) with their respective shifts to the number of beds available (up to ten). With the provided statistics and by varying the available parameters, an optimal solution can be obtained.

Some of the aspects of queuing discipline are not built into this model but could if so desired by changing a few lines within the macro. Balking was not addressed since few people have the choice of multiple hospitals or the ability to leave. Additionally, since this is a service scenario where lost sales are not the concern but instead adequate services is, costs were not analyzed. The purpose of the model is to determine the appropriate service time taking into consideration the patient load by varying the number of beds, nurses, and doctors.

Before demonstrating the capabilities of the queuing simulation model, a few key differences exist between the queuing model and the inventory distribution model and should be understood. The first key difference is how time was managed as previously discussed. Second, since the queuing problem does not contain separate levels of management (i.e., factory, warehouse, and dealer), the spreadsheet model did not initially

lend itself to the creation of completely separate macros. Instead, one large macro was programmed with several subroutines nested within the one macro. If desired, each subroutine could be developed into a separate macro. However, during the initial development it was found easier to work within one macro. As the complexity of the model was increased, the size of the individual macro grew. Towards the completion of the model, some of the advantages to a single macro were lost such as the inability to further name cells or use *Excel's* macro debug add-in. Therefore, if designing a more complex model or modifying this one, it would be advantageous to separate the macro into smaller macros.

To begin all scenarios, the user integrates with the queuing macro through a master worksheet in the same fashion as the inventory model. Dialog boxes will ask for initial input and the model will begin simulation. All pertinent data is transferred to the worksheet at the completion of the simulation.

C. SCENARIOS

With an understanding of queuing philosophy and "next event" time management, two scenarios will be simulated to demonstrate the full capability of the spreadsheet simulation model that was developed using Excel 4.0. Each will illustrate the benefits of using simulation for determining an optimal solution in a complex queuing environment in a hospital emergency room. Even if an optimal solution is not desired, a manager can pose "what if" scenarios and study the behavior of the queuing system. He/she can than make changes to the system to meet his/her desired objectives.

Without using simulation, a manager or director of a hospital emergency room would have few options for determining how many nurses, doctors, and beds are required to meet the anticipated patients' arrival rate. One option would be trial and error. His/her first iteration would be to compensate the demand by over-staffing the emergency room with

doctors and nurses for several weeks. After several weeks, sufficient data would accumulate allowing the manager to make further iterations by reducing staff size. His/her primary goal is the providing of adequate service with minimum patient waiting over a twenty-four hour period. After several months, the manager will achieve the service he/she desires. Unfortunately, with a changing environment and the practice of fluctuating staff size being economically unfeasible, the manager will view trial and error methods as a less than optimal approach. The following scenarios will illustrate how simulation is a far superior method than trial and error.

The first scenario will analyze the aforementioned trial and error method in that the manager approaches the problem by over-staffing the emergency room. During a one week period, ten beds, four nurses, and four doctors will be available full time to treat the patients in the emergency room. This simulation will show a gross under-utilization of the facilities. However, the simulation will provide the best service available and can be used as a point for other simulations. The second simulation will be a compilation of several one week simulations. Many "what if" scenarios will be simulated by varying the number of servers and beds available. Each change will be based upon the utilization and queuing results of previous scenarios. The goal of the second set of simulations is to obtain an optimal balance between adequate service and server utilization in a hospital emergency room. Also, another criterion will be to ensure that few patients wait for the use of a bed.

For all scenarios, the patient arrival rate was based upon a Poisson distribution with mean arrival rate varying during the day as shown in Figure 5.5. Treatment time was the same for each nurse and doctor and modeled upon a uniform distribution. The distribution of time varied by patient's category with a lower, upper, and standard deviation as shown in Table 5.1. Within the spreadsheet model, all of these values are inputted by the user and

can be changed to reflect actual data. To allow comparability between scenarios, only the numbers of beds, nurses, and doctors are altered.

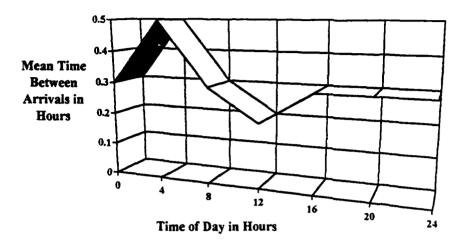

Figure 5.5: Patient Arrival Distribution

TABLE 5.1: PATIENT CATAGORIES AND TIME DISTRIBUTIONS

Patient Category	Description	% of Total	Lower	Upper	Standard Deviation
1	Open Wounds	8	0.25	0.35	1.0
2	Closed Injuries	13	0.20	0.30	1.0
3	Multiple Trauma	33	0.15	0.25	1.0
4	Visceral Complaints	20	0.10	0.20	1.0
5	Chronic Complaints	26	0.05	0.15	1.0

1. Full Services with No Optimization

As one would expect, under a full service environment with the given patient arrival rate as depicted in Figure 5.5, an under-utilization of the emergency room's facilities occurs as shown in Table 5.2. To understand the utilization rate of the emergency

room facilities, one must understand the simulation model. The model is designed to seek the nurse or doctor who has been without a patient for the longest amount of time resulting in the patient load being relatively evenly distributed among the staff. Having staff only

TABLE 5.2: SCENARIO 1—SERVER UTILIZATION

Nurse	Utilization	Doctor	Utilization	Bed	Utilization
1	17.65%	1	14.79%	ı	38.37%
2	7.03%	2	12.96%	2	19.07%
3	11.75%	3	10.66%	3	5.88%
4	11.49%	4	13.39%	4	0.82%
			•	5	0.13%
				6,7,8,9,10	0.00%

utilized less the 19% of the time is not economical to the hospital. For bed utilization, the model tries to fill whichever bed in not in use starting with the first bed and progressing to the tenth bed. Therefore, from Table 5.2, one can observe that only five beds are required with the fourth and fifth being used less than 1%. Table 5.3 provides other pertinent statistics of the full service queuing model. All show gross under-utilization of facilities.

TABLE 5.3: SCENARIO 1—SYSTEM UTILIZATION

Average Patients in System	1.125 Patients
Maximum Time in System	28.53 Minutes
Average Registration Oueue Length	0.00 Patients
Average Time in Registration Queue	0.00 Minutes
Maximum Time in Registration Queue	0.00 Minutes
Percent Who Wait for Registration	0.00 %
Average Bed Queue Length	0.00 Patients
Average Time in Bed Queue	0.00 Minutes
Maximum Time in Bed Queue	0.00 Minutes
Percent Who Wait for a Bed	0.00 %

From this simulation, the manager can understand much about the behavior of the system that will be used in further simulations. First, reduce the number of beds available from ten to at least five. One must be careful though because as the number of servers is reduced, the bed usage will correspondingly increase. The second behavior is the utilization of nurses and doctors. From this simulation, a manager can reduce the available resources by at least one nurse and one doctor. Ideally, he/she can reduce the staff to one nurse and doctor during off hours with augmentation of two or three of each during peak hours. All of these "what ifs" will be analyzed in the next section.

2. Limited Service with Optimization

The following scenario is a product of several "what if" scenarios. This process took several hours of computer time but it is still significantly more economical than trial and error methods over several months. The final values of utilization for nurses, doctors, and beds are based upon the author's judgment of what is believed to be an optimal solution. A professional hospital administrator would be able to apply this model to an actual hospital emergency room to which he/she could achieve an optimal solution based upon his/her expertise.

The final number of nurses, doctors, and beds that were modeled was two, two and five respectively. A nurse and doctor were available twenty-four hours a day while a second nurse and doctor were assigned during peak hours from 0800 to 1600. The five beds were available during the entire twenty-four hours. Table 5.4 presents the utilization of the emergency room facilities. The nurse's and doctor's utilization increases significantly from the first scenario but they are not over-utilized. Table 5.5 presents the statistics for the queuing environment. The length of time in the system along with the number of patients in the system increased but not to unreasonable values. Additionally, nobody had to wait for a bed and that was one of the criterion of the system.

TABLE 5.4: SCENARIO 2—SERVER UTILIZATION

Nurse	Utilization	Doctor	Utilization	Bed	Utilization
1	38.62%	1	40.35%	1	42.78%
2	30.70%	2	33.89%	2	23.31%
				3	6.71%
				4	1.14%
				5	0.36%

TABLE 5.5: SCENARIO 2—SYSTEM UTILIZATION

Average Patients in System	1.354 Patients
Maximum Time in System	72.05 Minutes
Average Registration Queue Length	0.106 Patients
Average Time in Registration Queue	1.992 Minutes
Maximum Time in Registration Queue	35.800 Minutes
Percent Who Wait for Registration	31.21 %
Average Bed Queue Length	0.00 Patients
Average Time in Bed Queue	0.00 Minutes
Maximum Time in Bed Queue	0.00 Minutes
Percent Who Wait for a Bed	0.00 %

Even with the above results, a manager must understand how those results are derived. These values are based upon a one week scenario derived from probabilistic data. Therefore, there is a range of randomness that exists which can cause some values to fluctuate. In Figure 5.6, the number of total patients in the system is illustrated. A number of peaks exist which do not necessarily correspond to the patient arrival rate as illustrated in Figure 5.5 or the number of nurses and doctors available. With probabilistic scenarios, patients will sometimes arrive only a few minutes apart leading to a temporary overload of the servers resulting in queues. This is the cause for a number of the peaks shown above.

Therefore, like an inventory management system, a hospital manager can include safety buffers within his/her ideal solution. Extra beds could be positioned in the emergency room and nurses and doctors can be put on call to handle unexpected increased workloads.

Even with an understanding that simulation methods do not produce a perfect answer, simulation does provide guidelines and an understanding of the behavior of a

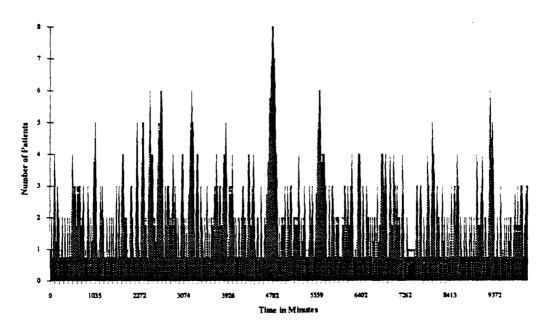

Figure 5.6: Patients in the Hospital Emergency Room

queuing system. Instead of the expensive approach of trial and error, a manager using a queuing system can apply simple modeling techniques to understand the behavior of a system and arrive at a plausible solution. Juxtaposing the solution with the manager's professional expertise will result in the optimal policy for a queuing environment. The next chapter will demonstrate how a manager can not only use spreadsheet simulation for inventory and queuing problems but also for approaching complex financial dilemmas.

VI. FINANCIAL BUDGETING

The previous two chapters focused on how spreadsheet simulation can be employed to resolve two very specific resource allocation predicaments: inventory distribution and queuing utilization. Not all managers will be confronted with either of these unique management dilemmas. However, virtually every manager is faced with the prospect of justifying his/her need for financial resources in the future. In corporate America and the Department of Defense, financial capital is a scarce resource that must be pleaded for and then allocated within an organization. The allocation justification process is an estimate, often itemized, of expected income and expense for a given period in the future or more succinctly known as financial budgeting. Estimation is the relevant term in the definition of budgeting that lends financial budgeting as an apropos subject for the discipline of simulation. Thus, this chapter will focus on resource allocation as it pertains to financial budgeting which is another facet of a successful manager's prowess.

A. THEORY

The creation of a financial budget is an integral part of any organization that will be confronted by every manager who is responsible for financial capital. The manager's performance is frequently judged upon his/her ability to submit a budget to management and then stay within its limits. Therefore, the methods employed by a manager when designing his/her segment of the budget is crucial to his/her viability as well as to the organization. Unfortunately, many aspects of budget formulation are not easily quantified. Interrelationships among cash flow items are not always clear, the operating environment is often turbulent, and predicting the future based upon historical data, trends, and managerial judgment are just a few of the factors that must be considered when a manager

takes on the task of budget formulation. So how does a manager create a budget and how can spreadsheet simulation simplify his/her quandary?

This chapter will assume that the reader understands basic budgeting methodology as only a few budgeting concepts that are relevant to the discussion will be introduced. There are essentially three levels of budgeting complexity [Ref. 2:p. 80]. The first is the most simplistic and is the foundation for the other two levels. This foundation level of budgeting is applicable to situations that entail little uncertainty in quantifying income or expense and in predicting the future. The manager will often employ a spreadsheet to develop the budget. He/she will categorize income and expenses onto the spreadsheet and project into the future. The summation or bottom line for the year constitutes the manager's budget. Therefore, the manager is using simple deterministic estimates to create a budget. This is called line item budgeting in the tusiness world. This method is frequently appropriate for many situations within a business. However, with more factors considered or a larger fraction of the business included in the budget, the line item budget becomes too inaccurate. Management will then cross into the second level of budgeting.

The second level of budgeting increases in complexity because it employs mathematical relationships to quantify interactions between variables. By identifying casual relationships, the manager accounts for important functional relationships among variables and significantly increases the accuracy of his/her budget. Mathematical relationships between different aspects of a business vary but are often segmented into fixed and variable costs. Fixed costs are similar to values used in line item budgeting. They are those that are part of the production expense that will occur even if no products are produced such as equipment depreciation. Thus, fixed costs do not vary during the year and are easily quantified. However, with variable costs, the manager's experience becomes a factor. An example of a variable cost is the expense of producing one product

such as the materials within the item. The manager's experience is required for variable costs because he/she must predict how many products will be produced. However, similar to line item budgeting the values that are included in formulation of the budget are still deterministic. Thus, the prediction about the future fails to quantify the uncertainty relating to the future. This is the key weakness of this method of budgeting. To resolve this dilemma, a manager will evoke the third level of budgeting.

The third level of budgeting is the most complex and is the point where spreadsheet simulation becomes essential to the solution. The third level employs probabilistic techniques to quantify uncertainty associated with future events. The remainder of this chapter will focus on how a second level spreadsheet budget can be augmented by simulation for a more realistic budget. However, there will never be a 100% correct answer because one can never fully predict the future.

To understand how simulation can be of benefit to the manager in the budgeting process, one must first be introduced to *Monte Carlo* methodology. The Monte Carlo technique can be defined as a method where a stochastic variable is assigned a value for use in a calculation by drawing a random value that is correlated to the probability distribution of the variable.

The Monte Carlo concept is best comprehended by a simplified example. A manager is requested to estimate sales of a particular product based upon his/her collective experience. He/she provides an optimistic prediction of 1000 units and pessimistic value of 500 units with a uniform distribution between these extremes. From this information, a uniform distribution is created that can be used in a Monte Carlo simulation. The pessimistic value is assigned a value of zero while the optimistic value is assigned a value of one. A random number is then generated between zero and one. If the random number was 0.3, a ratio between 500 and 1000 units will results in 650 units of sales.

The above example is a simplistic example of the Monte Carlo method but it illustrates the essential steps. First, a probability distribution is assigned to the variable of interest. There are several distributions to choose from such as uniform, triangular, normal, Poisson, and tabular to name a few. What distribution is best must be determined by collecting previous data that is normally surmised into a frequency distribution that can be correlated to an appropriate distribution. An appropriate caution must be stated before preceding any further. A significant assumption has been made when assigning a probability distribution based upon historical data. Monte Carlo methods are founded upon the assumption that the historical data with its corresponding distribution are in fact a true representation of the variable's interaction in the past and can be projected into the future. Otherwise, the model will produce results that are misleading and of no benefit to the analysts.

If the variable of interest is not quantifiable with past data, the probability distribution must originate from the manager. He/she must either estimate what he/she believes are the pessimistic, optimistic, and most likely values or chance occurrence for each range of possible values for each variable. This is not an easy task but it surpasses the alternative methods of intuition or trial and error

The second step of the Monte Carlo method is to assign the probability distribution a corresponding range of values from zero to one. The third step is to generate a random number from zero to one that is then applied to the probability distribution for a corresponding value that is then used in further calculations.

The fourth step is to perform steps three and four several times to allow the law of averages to work. The result is a range of values for the value of interest or objective variable such as total budget, net present value, etc. This range of values is then tabulated into a frequency distribution from which further analysis can be performed. The frequency

distribution is the paramount benefit of the Monte Carlo technique. Instead of one deterministic result, a range of values is presented to the manager that give the probability of achieving the objective. Thus, the manager can make a budgetary decision with significantly more confidence than the deterministic approach.

Thus, Monte Carlo methods offer several benefits to the manager when he/she is confronted with a complex financial budgeting dilemma. He/she can assign due weight to uncertain quantities and relationships vice relying totally on one deterministic value. Additionally, he/she has more information from which to base his/her decisions. Furthermore, Monte Carlo methods are relatively inexpensive to perform and can be easily adapted to a computer spreadsheet from which most budgets have their origins. The next section will discuss how a spreadsheet can be programmed to perform Monte Carlo simulation.

B. MONTE CARLO SIMULATION

A computer spreadsheet is relatively easily programmed through a macro to employ the Monte Carlo methods. The macro that was created with Excel 4.0 is much less intricate than the two previous chapter's macros and required the least amount of time to create. The only real difficulty encountered during programming was the creation of a method for the macro to be dynamically linked to the worksheet through variable names and cell reference without explicitly using the worksheet's name so as to make the macro applicable to any appropriate spreadsheet. Therefore, the Monte Carlo macro is fundamentally different from the inventory distribution or queuing utilization macros and can be applied to any spreadsheet that has probabilistic parameters with a desired objective. The macro has more applications than just financial budgeting and this makes it the most universal of the three macros developed during this study

A caveat must be understood before discussing the model. Monte Carlo simulation is not simulation in the same sense as inventory or queuing simulation. When a manager employs Monte Carlo methods, the results of the simulation are a frequency distribution of possible eventual outcomes that can be analyzed and used for decision analysis. However, this method does not demonstrate the *behavior* of the system as it changes over time which is the essential element of the previous two chapters. Therefore, Monte Carlo simulation is not true simulation but instead a sampling technique for determining probabilistic values for a crucial variable. These values can then be used in a true simulation model for a more realistic behavior analysis.

The development of the Monte Carlo macro begins with a flow chart that identifies key interactions within the model. Figure 6.1 depicts the events in the macro that begins with the identification of essential parameters and retrieval of data from the worksheet if it was previously saved. The next chain of events is to assign probabilistic variables on the spreadsheet with a respective probability distribution. Four distributions are offered in the macro: uniform, triangular, normal, and tabular. *Excel 4.0* is capable of several other distributions that can be programmed into the macro if so desired.

The next sequence of events is the heart of the Monte Carlo method. A random number is generated for each variable that is used to determine the variable's value from its corresponding probability distribution. After all variables have been assigned a value, the objective variable is recorded and relative frequency data is tabulated. This process repeats itself for the number of iterations chosen by the analyst.

Once the iterations are complete, the model transfers input data and the output statistics for further analysis to the worksheet if desired by the analyst. The worksheet is also returned to its original state by changing the manipulated variables to their original values. The Monte Carlo analysis of a worksheet is then complete.

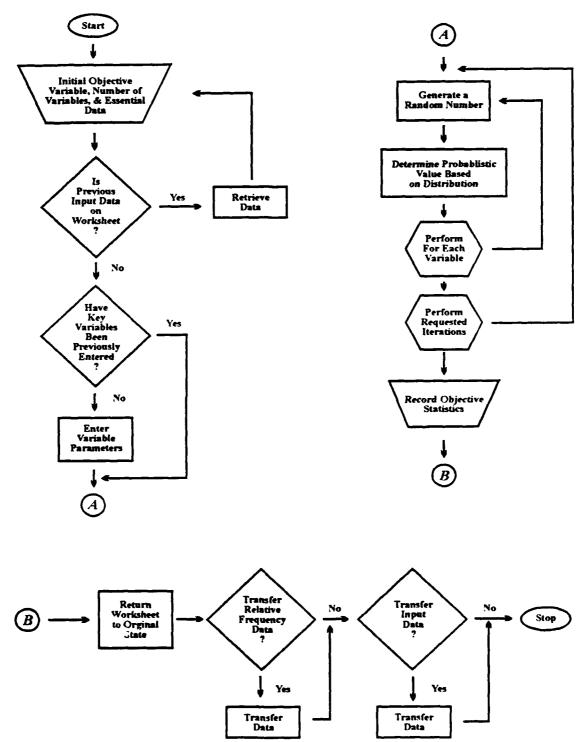

Figure 6.1: Monte Carlo Flow Chart

Key to the accuracy of the simulation is the number of iterations that were performed by the macro. There are no rules of thumb or mathematical methods for determining the number of iterations required to achieve accurate results. However, a method can be employed to ensure that results are consistent. First, the simulation is performed with a few iterations around a wide range of possible objective results. The resultant upper and lower limit from this limited simulation is then used in the next simulation run in which significantly more iterations are performed. A third run using more iterations is then compared to the second run. The frequency distribution comparison of each run should not be significantly different when plotted on the same axis. If they are, more iterations are required until the distributions are relatively equal.

With a Monte Carlo macro developed, the manager is ready to embark upon financial budgeting using Monte Carlo methods. To apply the macro, a few concepts must be built into the worksheet which contains the budget information. First, all essential variables that affect the objective must be included on the worksheet. Second, for each essential variable, it must be classified as either state, policy, or environmental. State and policy variables are not pertinent to the Monte Carlo macro. Environmental variables are the variables for which a probability distribution must be determined and modeled by the Monte Carlo method. The third step is to create the worksheet based on the previous two steps. Essential to the creation of the worksheet is to ensure that all variables and the objective are linked by formulas. Thus, as the environmental variables are changed by the macro, the objective also changes and statistics can be generated.

The above concepts are required for the proper execution of the Monte Carlo macro. The macro will perform the simulation with any worksheet designed in this manner. It does not have to be a financial budgeting scenario. Also, if one understands how the macro interacts with the worksheet, he/she can speed up the initial variable entry

process. The macro communicates to the user through *dialog boxes*. For each variable, a dialog box requests either the variable's cell location or name. The name function on the dialog box provides a list of all names for the worksheet. Thus, by naming all the environmental variables, the analyst does not have to search though the worksheet to locate a cell reference.

The Monte Carlo method and macro have now been introduced. To fully appreciate the benefits that can be rendered by these techniques, a financial budgeting scenario is modeled and simulated in the next section.

C. SCENARIO

The Department of Defense application of the Monte Carlo simulation method that was analyzed was the 1974 through 1976 budget of the Civilian Health and Medical Program for the Uniformed Services (CHAMPUS). All of the information that will be presented is derived from Maassen and Whipple [Ref. 4] and the following analysis does not attempt to verify or repute the reported results. Additionally, some simplifications were made to the worksheet so as not to make the model too complex.

Illustration 6.1 shows the budget for CHAMPUS as estimated for 1974 through 1976. A simplification of the derivation of the values included in Illustration 6.1 is present in Illustration 6.2. The 54 shaded areas on Illustration 6.2 are the environmental variables that are linked to Illustration 6.1 by the italicized variables. They affect the total budgeted obligation on Illustration 6.1 which is the objective value. The methods which the Navy used to derive these values are rudimentary and therefore lead one to question their accuracy. Additionally, the derivation of some of the values was not explained by Maassen and Whipple [Ref. 4].

For the straight line projection environmental variables, the values are based upon a determination of the percentage change that occurred during the previous year, 1973. No

Illustration 6.2: Derivation Values for CHAMPUS Budget

forecasting techniques were employed and the projection was held constant during the three years that were estimated in the budget. Inflation is also based upon a one year trend. The inflation that was experienced during 1973 was calculated and projected to be the same during the next two years with no inflation in the last year. The methods from which population was calculated were not provided by the reference.

The Monte Carlo financial budgeting scenario was performed by assigning probabilistic distribution to the forty-eight variables with total obligations as the objective. Since neither historic data nor CHAMPUS manager experience was available, there was no accurate method to determine appropriate distributions. Instead, reasonable variations around the actual values were used with uniform, triangular, and tabular distributions. This method demonstrates how a spreadsheet and Monte Carlo method can be applied for financial budgeting which is within the scope of this thesis. There was no attempt made to design a better CHAMPUS financial budgeting system which would require an anlaysis of sufficient historical data.

Figure 6.2 presents the frequency distribution for 500 and 750 iterations. The distribution appears reasonably stable thus sufficient iterations were performed. The distributions do not reflect any resemblance to factual data since the inputs were only theorized. However, Figure 6.2 does show the benefit of Monte Carlo simulation.

Instead of the deterministic values of \$527,383 as provided in Illustration 6.1, a range of values is depicted. For example, there is approximately a 80% chance that total obligation will exceed \$580,000 while only a 20% chance that it will exceed \$780,000. Furthermore, even though the inputted values are not factual but only a variation of the deterministic values, the probability of achieving a budget of \$527,383 is less than 10% in this scenario. This may explain why CHAMPUS consistently exceeds budget every year. The benefit of

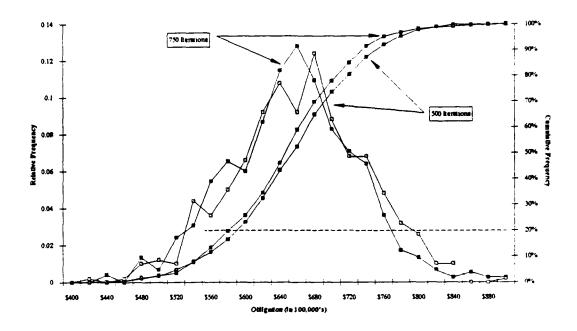

Figure 6.2: Total Simulated Obligations

this information is enormous. A manager does not have to base his/her judgment solely upon a single value but instead can weigh the probability of achieving a goal based upon a frequency distribution.

This scenario illustrates the benefit of Monte Carlo simulation in financial budgeting. As stated previously, this macro can also be applied in many other resource allocation scenarios. It is applicable to situations that involve uncertainty that can be reasonably quantified such as capital investment scenarios. The next chapter presents the summary and conclusions for this simulation method as well as the previous two chapters' simulations.

VII. SUMMARY AND CONCLUSIONS

The overall purpose of this study was to explore the possibility of applying digital computer spreadsheets as a sophisticated tool for resolving resource allocation enigmas. This involved a general discussion of simulation as a resource allocation tool and the methodology required to adapt a spreadsheet as a viable simulation device. To illustrate spreadsheet simulation, three separate and unique resource allocation scenarios were analyzed.

An inventory distribution system was the first allocation dilemma that was simulated. Several spreadsheet macros were created to fully analyze the behavior of the complex system. *Microsoft's Excel 4.0* was fully capable of the simulation task and many techniques that were created were used in the next two scenarios.

The second scenario was a queuing utilization analysis of a hospital emergency room. This model proved to be the most difficult to adapt to a spreadsheet due to the requirement of maintaining a vast data base on present and past events. However, through creative programming techniques, the spreadsheet was also capable of queuing simulation.

Financial budgeting through Monte Carlo methodology was the final simulation scenario analyzed. Adapting the spreadsheet for this scenario was the least difficult of the three. The result of Monte Carlo simulation is not true simulation as the produced result is a probability distribution vice a system behavior analysis. However, the Monte Carlo is the most adaptable of the three models as it is not as specific in design as the previous two models. It can be applied to a wide variety of resource allocation models.

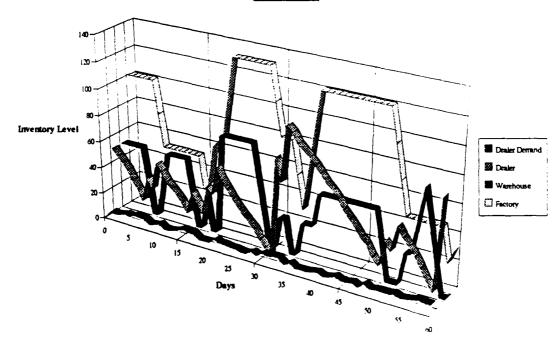

Simulation methodology for resource allocation is no longer limited to those who have access to simulation specific computer software. Spreadsheets, that are available to

virtually every manager, can be programmed in simulation methodology to analyze all but the most complex resource allocation enigma.

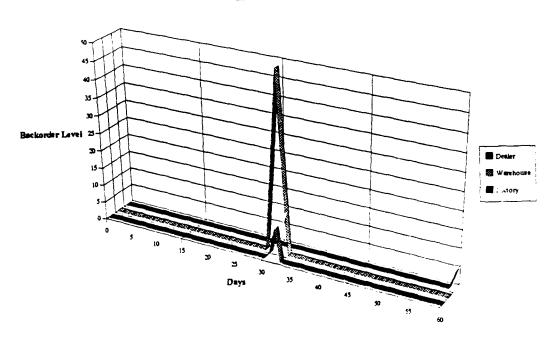

APPENDIX A INVENTORY DISTRIBUTION OUTPUT AND MACROS

SCENARIO ONE—ONE WAREHOUSE, NO USER INVOLVEMENT

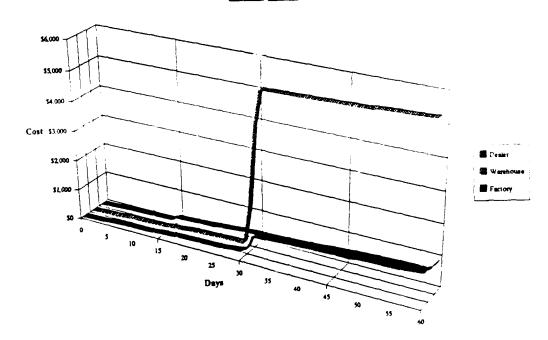

Initial Data	Dealer	Warehouse	Dealer
Beginning Inventory	50	50	100
Reorderr/Begin Production Level	25	25	35
Stop Production	*	*	100
